

Pass-Through, Welfare, and Incidence under Product Returns in Perfect Competition

Draft notes

July 21, 2026

1 Proposal

In markets without returns, consumer surplus and producer surplus are fully captured by the demand and supply curves, with producer surplus given by the area to the left of the supply curve up to the market price. This paper studies markets where consumers can return purchases and firms pay handling costs for returned items.

We show that with returns, consumer surplus is summarized by two aggregate objects: the gross demand curve and the overall return rate. All detailed heterogeneity across consumers—their tastes, match values, and return costs—matters only through these two curves. Producer surplus follows exactly the same geometric rule—area to the left of the supply curve—but the price that matters is no longer the list price. It is the net revenue the seller actually keeps per unit, namely the list price minus expected refunds and handling costs.

Consumers face the list price, but firms respond to the net revenue they retain. Standard pass-through logic therefore applies directly to net revenue. How much of a tax shows up in the consumer's list price is then determined by how net revenue changes when the list price changes. The classic result that it does not matter whether the seller or the buyer remits a tax no longer holds, because the return decision depends on which side pays the tax. The analysis yields simple summary measures for welfare and the division of tax burdens in markets with product returns.

2 Setting

A homogeneous product is sold at list price p . Consumers indexed by i differ in return hassle κ_i , the disutility from returning the product, and in match distribution G_i over post-purchase match quality u . After purchase, type i draws $u \sim G_i$ and keeps the item whenever $u - p \geq -\kappa_i$, earning surplus $u - p$, and returns it otherwise, earning $-\kappa_i$.

Buying at price p yields expected surplus

$$s_i(p) = \mathbb{E}_{u \sim G_i} [\max(u - p, -\kappa_i)].$$

For purchase, all consumer-side heterogeneity summarizes into willingness to pay v_i , defined by $s_i(v_i) = 0$, so type i buys if and only if $p \leq v_i$. Across types, $F(v) = \Pr(v_i \leq v)$, gross demand is $D(p) = 1 - F(p)$, and share $r(p)$ of gross units sold at p are returned.

The product market is perfectly competitive, producer j takes p as given, chooses output at cost $C_j(q_j)$, and pays handling cost $h > 0$ on each returned unit.

3 Consumer side

Write $s(v, p)$ for expected surplus at list price p among types with willingness to pay v , so $s(v, v) = 0$. Consumer surplus integrates surplus over all types who buy,

$$CS(p) = \int_p^\infty s(v, p) dF(v). \quad (1)$$

Differentiating in p gives an extensive-margin term from types entering or leaving the purchase margin and an intensive-margin term from lower surplus among inframarginal buyers,

$$CS'(p) = -s(p, p) f(p) + \int_p^\infty s_p(v, p) dF(v),$$

where $s_p(v, p) \equiv \partial s(v, p) / \partial p$ and f is the density of v_i when F is differentiable. On the extensive margin, $s(p, p) = 0$, so entry and exit contribute nothing at first order. On the intensive margin, $s_p(v, p)$ equals minus the keep probability, because a higher price harms the consumer only when she keeps the purchase,

$$s_p(v, p) = -\Pr(u \geq p - \kappa_i).$$

Aggregating over buyers who purchase then gives

$$CS'(p) = \int_p^\infty s_p(v, p) dF(v) = -D(p)(1 - r(p)),$$

by the definitions of $D(p)$ and $r(p)$. A small price change therefore satisfies

$$dCS = -D(p)(1 - r(p)) dp. \quad (2)$$

The extensive- and intensive-margin decomposition makes the local formula transparent. Consumer surplus changes depend only on the aggregates $D(p)$ and $r(p)$, both at each price and integrated along any path,

$$\Delta CS = - \int_{p_0}^{p_1} D(p)(1 - r(p)) dp.$$

Micro heterogeneity in price responses can be rich. Price p enters each $s_i(p)$ nonlinearly and can shift participation, return decisions, and inframarginal surplus differently across types. Yet once (D, r) are given, this microstructure is irrelevant for dCS and ΔCS . Two economies with the same paths of $D(p)$ and $r(p)$ deliver the same consumer surplus loss, whether high- v_i types adjust return behavior more steeply than low- v_i types or not. Only kept units enter at first order, through $1 - r(p)$, not gross purchases $D(p)$ alone.

Let $\bar{p}$ denote the highest willingness to pay in the population, so $D(\bar{p}) = 0$ and $CS(\bar{p}) = 0$. Integrating the local formula then rewrites consumer surplus as area under kept volume,

$$CS(p) = \int_p^{\bar{p}} D(z)(1 - r(z)) dz. \quad (3)$$

4 Supply side

Returns make list price an imperfect summary of producer payoffs. A gross sale brings revenue p if the consumer keeps the item and costs refund p plus handling h if the item is returned. Among

gross sales at list price p , share $r(p)$ are returned, so expected revenue per gross unit—the *effective marginal revenue*—is

$$\mu(p, h) \equiv p - r(p)(p + h). \quad (4)$$

Under perfect competition, firm j takes p as given and therefore faces a fixed number μ in its supply decision. At equilibrium, $\mu = \mu(p, h)$.

Given μ , firm j chooses output to solve

$$\max_{q_j \geq 0} \mu q_j - C_j(q_j), \quad \text{FOC: } C'_j(q_j) = \mu \text{ (if } q_j > 0),$$

with $C_j(0) = 0$. Write $q_j(\mu)$ for firm j 's supply, set to zero when μ is below its minimum marginal cost.

Summing across firms defines market supply and industry profit,

$$S(\mu) \equiv \sum_j q_j(\mu), \quad PS(\mu) \equiv \sum_j [\mu q_j(\mu) - C_j(q_j(\mu))]. \quad (5)$$

Which firms are active at each μ determines both the market quantity and total profit.

Differentiating $PS(\mu)$ with respect to μ gives, for each firm,

$$\frac{d}{d\mu} [\mu q_j - C_j(q_j)] = q_j + q'_j(\mu) [\mu - C'_j(q_j)].$$

Active firms satisfy $C'_j(q_j) = \mu$ at their chosen output, so the adjustment term $q'_j(\mu) [\mu - C'_j(q_j)]$ is zero for each firm—equivalently, the envelope theorem applied to each firm's profit problem gives $d\pi_j/d\mu = q_j(\mu)$. Summing over firms,

$$PS'(\mu) = \sum_j q_j(\mu) = S(\mu).$$

With no production at $\mu = 0$, it follows that industry profit equals the area to the left of the market supply curve,

$$PS(\mu) = \int_0^\mu S(z) dz. \quad (6)$$

At equilibrium $\mu = \mu(p, h)$, $PS = \int_0^{\mu(p, h)} S(z) dz$.

5 Failure of tax neutrality

Weyl and Fabinger (2013) show that without returns, buyer and seller remittance deliver the same equilibrium. With returns, we ask whether that equivalence survives by writing the two clearing conditions at a common checkout price p —the total payment at the register—and a per-unit tax τ . Fix p and τ . Seller remittance clears at

$$D(p) = S(p - \tau - r(p)(p + h)), \quad (7)$$

because both the return rate and per-return cost $p + h$ are evaluated at checkout price p . Buyer remittance clears at

$$D(p) = S((p - \tau) - r(p - \tau)(p - \tau + h)), \quad (8)$$

because the seller posts list price $p - \tau$, so returns and refund cost are evaluated there. The two conditions define the same equilibrium only if the arguments of $S(\cdot)$ coincide. Canceling $p - \tau$ yields

$$r(p)(p + h) = r(p - \tau)(p - \tau + h). \quad (9)$$

Result 1 (Failure of tax neutrality with returns). *Seller and buyer taxes define the same equilibrium if and only if $r(p)(p + h) = r(p - \tau)(p - \tau + h)$.*¹

Tax neutrality breaks down with product returns because the refunded amount—and therefore the keep-or-return decision—depends on which side of the market remits the tax. Under seller remittance, the checkout price (which includes the tax) is refunded, so consumers decide whether to return based on that tax-inclusive price. Under buyer remittance, the seller posts a pre-tax list price, only that list price is refunded, and the return decision is based on this lower, tax-exclusive price. Even though the total checkout price and the tax are identical in both regimes, the return rate and the seller’s refund liability per return are evaluated at different prices (p versus $p - \tau$).

The direction in which the return rate changes is ambiguous—a higher price can make each individual more likely to return but can also select consumers with stronger purchase intentions who are less likely to return—so $r(p)$ may be above or below $r(p - \tau)$. Regardless of the direction, the seller’s effective marginal revenue generally differs, so the two tax regimes produce distinct market-clearing conditions and are not equivalent. The fundamental cause is that the purchase decision is always based on the checkout price, while the return decision uses the tax-inclusive price under seller remittance and the tax-exclusive price under buyer remittance, creating a wedge that alters equilibrium.

6 Pass-through

Write $Q \equiv D(p)$. We first study pass-through for two cost shocks: a uniform increase in marginal production cost (denoted c) and an increase in the per-unit handling cost h ; the same framework is then extended to a per-unit tax. A uniform production-cost increase means adding one dollar to each firm’s marginal cost $C'_j(q_j)$ at every output level. Production cost and handling cost hit equilibrium on different margins. Production cost shifts market supply at a given μ without moving μ at fixed list price. Handling cost moves μ through (4) at fixed list price without shifting supply at a given μ .

Equilibrium satisfies

$$m(p, x) \equiv D(p) - S(\mu(p, x), x) = 0, \quad x \in \{c, h\}. \quad (10)$$

Differentiating while keeping $m = 0$ defines pass-through $\rho_x \equiv dp/dx$ by

$$\rho_x = -\frac{m_x}{m_p}, \quad (11)$$

where $m_p \equiv \partial m / \partial p$ and $m_x \equiv \partial m / \partial x$. Since $m = D - S$,

$$m_p = D'(p) - S'(\mu) \mu_p, \quad m_x = -S'(\mu) \mu_x - S_x, \quad (12)$$

with $\mu_p \equiv d\mu/dp$, $\mu_x \equiv \partial\mu/\partial x$ at fixed p , $S'(\mu) \equiv dS/d\mu$, and $S_x \equiv \partial S/\partial x$ at fixed μ . Hence

$$\rho_x = \frac{S'(\mu) \mu_x + S_x}{D'(p) - S'(\mu) \mu_p}. \quad (13)$$

¹Neutrality requires the return wedge to be the same at checkout price p and at posted list price $p - \tau$. That holds for all taxes only if $r(p)(p + h)$ is constant in posted list price, which requires $r(p) = C/(p + h)$ for some constant C ; without that functional form on r , the two clearing conditions need not define the same equilibrium.

At fixed list price p , a one-dollar parallel rise in production cost shifts supply at fixed μ , so $\mu_c = 0$ and $S_c = -S'(\mu)$. A one-dollar rise in handling cost moves μ by $r(p)$ per gross unit sold and does not shift supply at fixed μ , so $\mu_h = -r(p)$ and $S_h = 0$. Hence

$$\mu_c = 0, \quad S_c = -S'(\mu), \quad \mu_h = -r(p), \quad S_h = 0. \quad (14)$$

Substituting into (13) yields

Result 2 (Pass-through of production and handling costs).

$$\frac{\rho_h}{\rho_c} = r(p), \quad (15)$$

with pass-through into list price

$$\rho_c = \frac{-S'(\mu)}{D'(p) - S'(\mu) \mu_p}, \quad \rho_h = r(p) \rho_c. \quad (16)$$

A one-dollar increase in production cost is equivalent to decreasing μ by one unit. Market clearing $D(p) = S(\mu)$ translates a given change in μ into list price through the same local comparative statics. Handling moves μ by only $r(p)$ per dollar relative to that unit shift, so $\rho_h/\rho_c = r(p)$. When $r \equiv 0$, handling does not move μ and ρ_c coincides with the textbook competitive pass-through formula.

Write p^s for checkout price under seller remittance and p^b for checkout price under buyer remittance; let $\rho_\tau^s \equiv dp^s/d\tau$ and $\rho_\tau^b \equiv dp^b/d\tau$. For a local change at $\tau = 0$, tax pass-through is (13) with $S_\tau = 0$: the denominator uses the same μ_p as above, and the only difference across remittance regimes is $\mu_\tau^s \equiv \partial\mu^s/\partial\tau$ versus $\mu_\tau^b \equiv \partial\mu^b/\partial\tau$ at fixed checkout price:

$$\rho_\tau^s = \frac{S'(\mu) \mu_\tau^s}{D'(p^s) - S'(\mu) \mu_p}, \quad \rho_\tau^b = \frac{S'(\mu) \mu_\tau^b}{D'(p^b) - S'(\mu) \mu_p}. \quad (17)$$

At $\tau = 0$,

$$\mu_\tau^s = -1, \quad \mu_\tau^b = r(p^b) + (p^b + h) r'(p^b) - 1. \quad (18)$$

Under seller remittance, $\mu_\tau^s = -1$ at fixed checkout price, so $\rho_\tau^s = \rho_c$. Under buyer remittance, μ_τ^b differs, so tax pass-through generally differs from ρ_c .

7 Incidence

With the pass-through results in hand, we can now compute the welfare effect of each cost shifter and the division of the loss between consumers and producers. Throughout, $Q \equiv D(p)$ and $r \equiv r(p)$ denote the equilibrium gross quantity and the return rate. From the consumer-side analysis, a small increase in any shifter x changes consumer surplus by

$$\frac{dCS}{dx} = -Q(1 - r) \rho_x, \quad (19)$$

where $\rho_x \equiv dp/dx$ is the pass-through of the shock into the list price.

Producer surplus is less immediate because a shock may shift the supply schedule directly as well as indirectly through the effective marginal revenue μ . Let $S(\mu, x)$ be the market supply curve,

where the second argument allows for a direct effect of x on firms' costs, and write producer surplus as $PS(\mu, x) = \int_0^\mu S(z, x) dz$. Differentiating with respect to x ,

$$\frac{dPS}{dx} = S(\mu, x) \frac{d\mu}{dx} + \int_0^\mu \frac{\partial S(z, x)}{\partial x} dz.$$

Using the equilibrium condition $S(\mu, x) = Q$ and denoting $\Sigma_x \equiv \int_0^\mu (\partial S(z, x)/\partial x) dz$, we obtain

$$\frac{dPS}{dx} = Q \frac{d\mu}{dx} + \Sigma_x = Q(\mu_p \rho_x + \mu_x) + \Sigma_x, \quad (20)$$

with $\mu_p \equiv \partial\mu/\partial p$ and $\mu_x \equiv \partial\mu/\partial x$ evaluated at fixed list price.

The term Σ_x captures the direct shift of the supply curve holding μ constant. A uniform, parallel increase in every firm's marginal production cost by one dollar ($x = c$) moves the supply curve inward according to $\partial S(\mu, c)/\partial c = -S'(\mu)$, so $\Sigma_c = \int_0^\mu (-S'(z)) dz = -S(\mu) = -Q$. For a handling-cost shock h or a per-unit tax (whether seller- or buyer-remitted), the supply schedule at a given μ is unchanged, hence $\Sigma_h = \Sigma_{\tau_s} = \Sigma_{\tau_b} = 0$. The partial derivatives μ_x are obtained directly from the definition of effective marginal revenue: $\mu_c = 0$, $\mu_h = -r$, $\mu_{\tau_s} = -1$, and, for the buyer-remitted tax evaluated at $\tau = 0$, $\mu_{\tau_b} = r + (p + h)r' - 1$ as derived in Section 5.

Substituting these values together with the pass-through expressions $\rho_h = r\rho_c$ and $\rho_\tau^s = \rho_c$ into (20) yields the producer-surplus responses:

$$\frac{dPS}{dc} = Q(\mu_p \rho_c - 1), \quad (21)$$

$$\frac{dPS}{dh} = Q(\mu_p \rho_h - r), \quad (22)$$

$$\frac{dPS}{d\tau_s} = Q(\mu_p \rho_c - 1), \quad (23)$$

$$\frac{dPS}{d\tau_b} = Q(\mu_p \rho_\tau^b + \mu_{\tau_b}). \quad (24)$$

The incidence ratio $I(x) \equiv |dCS/dx|/|dPS/dx|$ measures how the total loss is divided. For production cost, handling cost, and the seller-remitted tax, the ratio simplifies to the same expression:

$$I(c) = I(h) = I(\tau_s) = \frac{(1 - r) \rho_c}{1 - \mu_p \rho_c}. \quad (25)$$

For the buyer-remitted tax, the ratio is

$$I(\tau_b) = \frac{(1 - r) \rho_\tau^b}{-(\mu_p \rho_\tau^b + \mu_{\tau_b})}, \quad \mu_{\tau_b} = r + (p + h)r' - 1. \quad (26)$$

Equation (25) generalises the standard competitive-market formula $I = \rho/(1 - \rho)$ (Weyl and Fabinger, 2013). Consumer loss is scaled by the keep probability $1 - r$, and the producer-side denominator involves the effective-revenue pass-through $\mu_p \rho_c$ rather than the list-price pass-through alone. Production cost, handling cost, and a seller-remitted tax all generate the same incidence split because none of them changes the price at which consumers decide whether to return the product; they shift equilibrium exclusively through the effective marginal revenue μ . The buyer-remitted tax, in contrast, alters the refund price to the pre-tax list price, so the return rate and the per-return refund liability differ. This breaks the symmetry, giving an incidence ratio that departs from (25)—a welfare counterpart to the tax-neutrality failure established earlier. When returns are absent ($r = 0$, $\mu_p = 1$, $\rho_\tau^b = \rho_c$), all four ratios collapse to $\rho_c/(1 - \rho_c)$, restoring the familiar equivalence.
